Relationship between sample size and architecture for the estimation of Sobolev functions using deep neural networks

Stéphane Chrétien

University of Lyon 2
ERIC Laboratory

MLOMA, Clermont Ferrand 21 décembre 2023
Modern machine learning and statistics deal with the problem of learning from data:

- given a training dataset \((y_i, x_i) \ i \in I\) where
  - \(x_i \in \mathbb{R}^d\) is the input
  - \(y_i \in \mathbb{R}\) is the output,

one seeks a function \(f : \mathbb{R}^d \mapsto \mathbb{R}\) from a certain function class \(\mathcal{F}\) that has good prediction performance on test data \((y_t, x_t), \ t \in T\), i.e. which has small testing error

\[
\sum_{t \in T} \ell(y_t, f(x_t)) \tag{1}
\]
For this purpose, we often solve the (possibly penalised) following problem on the training dataset

\[
\sum_{i=1}^{n} \ell(y_t, f(x_t)) + \text{pen}(f) \tag{2}
\]

and hope that the estimator \( \hat{f} \) will generalise well on unobserved data.
This problem is of fundamental significance and finds applications in numerous scenarios.

For instance, in image recognition,

- the input $x$ corresponds to the raw image
- the output $y$ is the image category

and the goal is to find a mapping $f$ that can classify new images with acceptable accuracy.

Decades of research efforts in statistical machine learning have been devoted to developing methods to find $f$ efficiently with provable guarantees.
○ Prominent examples include

  ○ linear classifiers (e.g., linear / logistic regression, linear discriminant analysis),
  ○ kernel methods (e.g., support vector machines),
  ○ tree-based methods (e.g., decision trees, random forests),
  ○ nonparametric regression (e.g., nearest neighbors, local kernel smoothing), etc.

○ Roughly speaking, each aforementioned method corresponds to a different function class $\mathcal{F}$ from which the final classifier $f$ is chosen.
Deep learning, in its simplest form, consists in looking for functions of the form

\[ \mathcal{F} = \left\{ f(x, \theta) = W_L(\sigma_L(W_{L-1}(\sigma_{L-1}(\cdots \sigma_2(W_1(x)))))) \right\} \]

where \( \sigma_l \) is a non-linear function which applies componentwise and \( W_l \) is an affine operator, \( l = 1, \ldots, L \).

Note that this general architecture does not work without specific tweaks and tricks

(convolutions, initialisation, dropout, batch normalisation, layerwise normalisation, etc . . . ).
Deep learning is able to approximate complicated nonlinear maps through composing many simple nonlinear functions.

The motivation for the multilayer architecture is that there are different levels of features and the layers might be able to properly account for these different levels independently.

Here, we sample and visualize weights from a pre-trained AlexNet model.
This can be used to generate new images using for instance, Generative Adversarial Networks or Diffusion models.

It is widely acknowledged that two indispensable factors contribute to the success of deep learning, namely

- **huge datasets** that often contain millions of samples and
- **immense computing power** resulting from clusters of graphics processing units (GPUs).

Admittedly, these resources are only recently available.
However, these two alone are not sufficient to explain the mystery of deep learning:

- Why is over-parametrization not a problem?
  - Overparametrisation should lead to overfitting,

- BUT ... this is not what we always observe in practice!
and

- nonconvexity does not seem to be a problem: even with the help of GPUs, training deep learning models is still NP-hard in the worst case due to the highly nonconvex loss function to minimize.

- Nevertheless, standard incremental algorithms (Stochastic Gradient Descent, etc) often reach good minimisers of the Empirical Risk

- A lot remains to be understood! ...
Why overparametrise, to begin with?
Why overparametrise, to begin with?

- It is often observed that depth helps efficiently extract features at different scales from the inputs,
- recent studies found that *increasing both depth and width in a shallow model leads to very nice continuous limits*, where *PDE tools can be put to work*...
- Networks with wide layers (larger than sample size) enjoy connectivity of the minimisers (Nguyen 2019)

See Figure 1 below from Garipov et al. 2018 for an illustration. Solutions A and B have low cost but the line connecting them goes through solutions with high cost. But we can find C of low cost such that paths AC and CB only pass through low-cost region.
Why overparametrise, to begin with?

- Recent interesting work by Bubeck and Sellke states that overparametrisation is key to robustness

**Abstract**

Classically, data interpolation with a parametrized model class is possible as long as the number of parameters is larger than the number of equations to be satisfied. A puzzling phenomenon in deep learning is that models are trained with many more parameters than what this classical theory would suggest. We propose a theoretical explanation for this phenomenon. We prove that for a broad class of data distributions and model classes, overparametrization is necessary if one wants to interpolate the data smoothly. Namely we show that smooth interpolation requires $d$ times more parameters than mere interpolation, where $d$ is the ambient data dimension. We prove this universal law of robustness for any smoothly parametrized function class with polynomial size weights, and any covariate dist-
Potentially bad consequences of overparametrisation?
What are the bad consequences of overparametrisation?

- When some of the layers are not wide, over-parametrization usually entails existence of many local minimisers with potentially different statistical performance.
  - Common practice advises to run stochastic gradient descent with random initialization and converges to parameters with very good practical prediction accuracy.
    - Why is this simple approach actually often working?
- Overfitting should take place in full generality
  - Does the optimisation algorithm help find better networks?

The goal of current research is to resolve these paradoxes!
Generalisation bounds
"Old" but we interesting work by Bartlett, Barron and others...

Theorem (B., Foster, Telgarsky, 2017)

With high probability over $n$ training examples $(X_1, Y_1), \ldots, (X_n, Y_n) \in X \times \{\pm 1\}$, every $f_W$ with $R_W \leq r$ has

$$
\Pr(\text{sign}(f(X)) \neq Y) \leq \frac{1}{n} \sum_{i=1}^{n} 1[Y_i f(X_i) \leq \gamma] + \tilde{O} \left( \frac{rL}{\gamma \sqrt{n}} \right).
$$

Here, $f_W$ is computed in a network with $L$ layers and parameters $W_1, \ldots, W_L$:

$$
f_W(x) := \sigma_L(W_L \sigma_{L-1}(W_{L-1} \cdots \sigma_1(W_1 x) \cdots)),
$$

where the $\sigma_i$ are 1-Lipschitz, and we measure the scale of $f_W$ using a product of norms of the matrices $W_i$, for example, $r := \prod_{i=1}^{L} \|W_i\|_* \left( \sum_{i=1}^{L} \frac{\|W_i\|_2^{2/3}}{\|W_i\|_*^{2/3}} \right)^{3/2}$.

New trends involve PAC-Bayes bounds and compression

Stronger generalization bounds for deep nets via a compression approach

Sanjeev Arora* Rong Ge† Behnam Neyshabur† Yi Zhang§

Abstract

Deep nets generalize well despite having more parameters than the number of training samples. Recent works try to give an explanation using PAC-Bayes and Margin-based analyses, but do not as yet result in sample complexity bounds better than naive parameter counting. The current paper shows generalization bounds that’re orders of magnitude better in practice. These rely upon new succinct reparametrizations of the trained net — a compression that is explicit and efficient. These yield generalization bounds via a simple compression-based framework introduced here. Our results also provide some theoretical justification for widespread empirical success in compressing deep nets.

Analysis of correctness of our compression relies upon some newly identified “noise stability” properties of trained deep nets, which are also experimentally verified. The study of these properties and resulting generalization bounds are also extended to convolutional nets, which had eluded earlier attempts on proving generalization.
New trends involve PAC-Bayes bounds and compression
Double Descent and Benign overfitting
○ Overparametrisation might work although it contradicts the intuition that ”overfitting hurst generalisation”

○ Now, one often speaks of ”interpolation” and one hopes that it does not hurt generalisation;

○ When this holds, one speaks of **Benign Overfitting**.
Montanari et al. **resolved this paradox ... for the linear model!**

Does data interpolation contradict statistical optimality?

Mikhail Belkin  Alexander Rakhlin  Alexandre B. Tsybakov
The Ohio State University  MIT  CREST, ENSAE

Abstract

We show that learning methods interpolating the training data can achieve optimal rates for the problems of nonparametric regression and prediction with square loss.

1 Introduction

In this paper, we exhibit estimators that interpolate the data, yet achieve optimal rates of convergence for the problems of nonparametric regression and prediction with square loss. This curious observation goes against the usual (or, folklore?) intuition that a good statistical procedure should forego the exact fit to data in favor of a more smooth representation. The family of estimators we consider do exhibit a bias-variance trade-off with a tuning parameter, yet this “regularization” co-exists in harmony with data interpolation.

Motivation for this work is the recent focus within the machine learning community on the out-of-sample performance of neural networks. These flexible models are typically trained to fit the data exactly (either in their sign or in the actual value), yet they predict well on unseen data. The conundrum has served both as a source of excitement about the “magical” properties of neural networks, as well as a call for the development of novel statistical techniques to resolve it.

The aim of this short note is to show that not only can interpolation be a good statistical procedure, but it can even be optimal in a minimax sense. To the best of our knowledge, such optimality has not been exhibited before.

Let \((X,Y)\) be a random pair on \(\mathbb{R}^d \times \mathbb{R}\) with distribution \(P_{XY}\), and let \(f(x) = \mathbb{E}[Y|X = x]\) be the regression function. A goal of nonparametric estimation is to construct an estimate \(\hat{f}_n\) of \(f\), given a sample \((X_1, Y_1), \ldots, (X_n, Y_n)\) drawn independently from \(P_{XY}\). A classical approach to this problem is based on minimizing the empirical risk. However, we prove that \(\hat{f}_n = X\) is optimal.
Benign overfitting already occurs in traditional statistics

The Nadaraya-Watson estimator for a singular kernel $K$ is defined as

$$f_n(x) = \begin{cases} 
Y_i & \text{if } x = X_i \text{ for some } i = 1, \ldots, n, \\
0 & \text{if } \sum_{i=1}^{n} K\left(\frac{x-X_i}{h}\right) = 0, \\
\frac{\sum_{i=1}^{n} Y_i K\left(\frac{x-X_i}{h}\right)}{\sum_{i=1}^{n} K\left(\frac{x-X_i}{h}\right)} & \text{otherwise.}
\end{cases}$$

Interpolation with $K(u) = \|u\|^{-a} I\{\|u\| \leq 1\}$, $a = 0.49$, and various values of $h$.

Figure: Singular Kernel estimators that interpolate!
The Nadaraya-Watson estimator for a singular kernel $K$ is defined as

$$f_n(x) = \begin{cases} 
Y_i & \text{if } x = X_i \text{ for some } i = 1, \ldots, n, \\
0 & \text{if } \sum_{i=1}^{n} K\left(\frac{x-X_i}{h}\right) = 0, \\
\frac{\sum_{i=1}^{n} Y_i K\left(\frac{x-X_i}{h}\right)}{\sum_{i=1}^{n} K\left(\frac{x-X_i}{h}\right)} & \text{otherwise}.
\end{cases}$$

**Theorem (Belkin, Rahklin and Tsybakov (2019))**

The Nadaraya Watson estimator achieves the **minimax pointwise risk** over certain Holder classes. *(And thus, you cannot do essentially better!)*

Abstract

The power of neural networks lies in their ability to generalize to unseen data, yet the underlying reasons for this phenomenon remain elusive. Numerous rigorous attempts have been made to explain generalization, but available bounds are still quite loose, and analysis does not always lead to true understanding. The goal of this work is to make generalization more intuitive. Using visualization methods, we discuss the mystery of generalization, the geometry of loss landscapes, and how the curse (or, rather, the blessing) of dimensionality causes optimizers to settle into minima that generalize well.

1 Introduction

Neural networks are a powerful tool for solving classification problems. The power of these models is due in part to their expressiveness; they have many parameters that can be efficiently optimized to fit nearly any finite training set. However, the real power of neural network models comes from their ability to generalize; they often make accurate predictions on test data that were not seen during training, provided the test data is sampled from the same distribution as the training data.

The generalization ability of neural networks is seemingly at odds with their expressiveness. Neural network training algorithms work by minimizing a loss function that measures model performance using only training data. Because of their flexibility, it is possible to find parameter configurations

Empirical discovery

On a set of experimental problems Tom Goldstein and collaborators have empirically discovered that the basins surrounding good minima have a volume at least 10,000 orders of magnitude larger than that of bad minima (!!!), rendering it impossible to stumble upon bad minima in practice.
Do local optimisers communicate with each other?
Global Minima of Overparameterized Neural Networks

Author: Yaim Cooper

Abstract

We explore some mathematical features of the loss landscape of overparameterized neural networks. A priori, one might imagine that the loss function looks like a typical function from $\mathbb{R}^d$ to $\mathbb{R}$, in particular, that it has discrete global minima. In this paper, we prove that in at least one important way, the loss function of an overparameterized neural network does not look like a typical function. If a neural network has $d$ parameters and is trained on $n$ data points $(x_i, y_i) \in \mathbb{R}^d \times \mathbb{R}$, with $d > rn$, we show that the locus...
A big mystery about deep learning is how, in a highly nonconvex loss landscape, gradient descent often finds near-optimal solutions those with training cost almost zero—even starting from a random initialization.

This can be explained by this very counterintuitive phenomenon:

**Empirical discovery**

*(Freeman and Bruna, 2016, Garipov et al. 2018, Draxler et al. 2018)* All pairs of low-cost solutions found via gradient descent can actually be connected by simple paths in the parameter space, such that every point on the path is another solution of almost the same cost. In fact the low-cost path connecting two near-optima can be piecewise linear with two line-segments, or a Bezier curve.

Abstract

*Mode connectivity* ([Garipov et al., 2018; Draxler et al., 2018]) is a surprising phenomenon in the loss landscape of deep nets. Optima—at least those discovered by gradient-based optimization—turn out to be connected by simple paths on which the loss function is almost constant. Often, these paths can be chosen to be piece-wise linear, with as few as two segments.

We give mathematical explanations for this phenomenon, assuming generic properties (such as dropout stability and noise stability) of well-trained deep nets, which have previously been identified as part of...
Landscape connectivity (borrowed from blog post by R. Ge)

Figure: Landscape connectivity!
Theorem

If two trained multilayer ReLU nets with the same architecture are \( \epsilon \)-dropout stable, then they can be connected in the loss landscape via a piece-wise linear path in which the number of linear segments is linear in the number of layers, and the loss of every point on the path is at most \( \epsilon \) higher than the loss of the two end points.

Figure: Connectivity via dropout-stability!
Theorem

If two trained multilayer ReLU nets with the same architecture are $\epsilon$-noise stable, then they can be connected in the loss landscape via a piece-wise linear path with at most 10 segments, and the loss of every point on the path is at most $\epsilon$ higher than the loss of the two end points.
Striking properties of stochastic gradient descent

Wide Neural Networks of Any Depth Evolve as Linear Models Under Gradient Descent

Jaehoon Lee*, Lechao Xiao*, Samuel S. Schoenholz, Yasaman Bahri, Jascha Sohl-Dickstein, Jeffrey Pennington

Abstract

A longstanding goal in deep learning research has been to precisely characterize training and generalization. However, the often complex loss landscapes of neural networks have made a theory of learning dynamics elusive. In this work, we show that for wide neural networks the learning dynamics simplify considerably and that, in the infinite width limit, they are governed by a linear model obtained from the first-order Taylor expansion. In this regime, systems can often shed light on these hard problems. For neural networks, one such limit is that of infinite width, which refers either to the number of hidden units in a fully-connected layer or to the number of channels in a convolutional layer. Under this limit, the output of the network at initialization is a draw from a Gaussian process (GP); moreover, the network output remains governed by a GP after exact Bayesian training using squared loss (Neal, 1994; Lee et al., 2018; Matthews et al., 2018; Novak et al., 2019; Garriga-Alonso et al., 2018). Aside from its theoretical simplicity, the infinite-width limit is also of practical inte-
...but more is actually happening! An asymptotical phenomenon shows that:

Wide Neural Networks of Any Depth
Evolve as Linear Models Under Gradient Descent

Jaehoon Lee*12, Lechao Xiao*12, Samuel S. Schoenholz1, Yasaman Bahri1, Jascha Sohl-Dickstein1, Jeffrey Pennington1

Abstract

A longstanding goal in deep learning research has been to precisely characterize training and generalization. However, the often complex loss landscapes of neural networks have made a theory of learning dynamics elusive. In this work, we show that for wide neural networks the learning dynamics simplify considerably and that, in the infinite width limit, they are governed by a linear model obtained from the first-order Taylor expansion of the network output.

Systems can often shed light on these hard problems. For neural networks, one such limit is that of infinite width, which refers either to the number of hidden units in a fully-connected layer or to the number of channels in a convolutional layer. Under this limit, the output of the network at initialization is a draw from a Gaussian process (GP); moreover, the network output remains governed by a GP after exact Bayesian training using squared loss (Neal, 1994; Lee et al., 2018; Matthews et al., 2018; Novak et al., 2019; Garriga-Alonso et al., 2018). Aside from its theoretical simplicity, the infinite-width limit is also of practical interest.

Gradient descent is then shown to converge exponentially quickly to a closeby interpolator.
o Width helps simplify the analysis
o Recent works of Jaquot et al. says it then reduces Deep Neural Networks to a tangent kernel method whose feature map corresponds to the gradient of the network at a random initialisation . . .
○ Width helps simplify the analysis
○ Recent works of Jaquot et al. Chizat, Oyallon and Bach says that this phenomenon of exponential speed is a phenomenon that takes place in a much larger setting . . .

Abstract

In a series of recent theoretical works, it was shown that strongly over-parameterized neural networks trained with gradient-based methods could converge exponentially fast to zero training loss, with their parameters hardly varying. In this work, we show that this “lazy training” phenomenon is not specific to over-parameterized neural networks, and is due to a choice of scaling, often implicit, that makes the model behave as its linearization around the initialization, thus yielding a model equivalent to learning with positive-definite kernels. Through a
Other interesting property of gradient descent: implicit bias
○ Implicit bias of gradient descent

○ For minimising a function $F(\theta)$, one can use the gradient method:

$$\theta^{(l+1)} = \theta^{(l)} - \eta_l \nabla F(\theta^{(l)})$$  \hspace{1cm} (3)
○ if there is a unique global minimizer $\theta^*$, then the goal of optimization algorithms is to find this minimizer,

○ when there are multiple minimizers (thus for a function which cannot be strongly convex ), one can easily show that

$$F(\theta_t) - \inf_{\theta \in \mathbb{R}^d} F(\theta)$$

is converging to zero.
Implicit bias of gradient descent

- With some extra assumptions, we can show that the algorithm is converging to one of the multiple minimizers of $F$
  - note that when $F$ is convex, this set is also convex.
- But ... which one?
Implicit bias of gradient descent

- This is what is referred to as the implicit regularization property of certain optimization algorithms, and in particular, gradient descent and its variants.

- This is interesting in overparametrised machine learning because there usually are many minimizers.

- In a nutshell, gradient descent usually leads to minimum $\ell_2$-norm solutions.

- This shows that the chosen empirical risk minimizer is not arbitrary!
A slightly more general nonlinear regression setup: ridge functions

(work with Emmanuel Caron, Univ. Avignon, France)
Mathematical Model

Let $Z_i = (X_i, Y_i)$ in $\mathbb{R}^{d+1} \times \mathbb{R}$, $i = 1, \ldots, n$ be observations drawn from the following model

$$Y_i = f^*(X_i) + \varepsilon_i \quad (5)$$

$i = 1, \ldots, n$, where we assume that

- the vectors $X_i$, $i = 1, \ldots, n$ are random and i.i.d., taking values in $\mathbb{R}^d$
- the values $\varepsilon_i$, $i = 1, \ldots, n$ are the random observation errors.

The goal is to estimate $f^*$ based on the observation $Z_1, \ldots, Z_n$.

The estimation of $f^*$ will be based on restricting the search to a subset $F$ of functions of a Banach space $\mathcal{B}$. 
In order to generalise, the estimator should be chosen in the set of stationary points of the empirical version of the risk $\mathcal{R} : \mathcal{F} \to \mathbb{R}$ defined by

$$\mathcal{R}(f) = \mathbb{E} [\ell(Y, f(X))],$$

where $\ell : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$ satisfies

- $\ell(y, y) = 0$ for all $y \in \mathbb{R}$ and
- $\ell(y, \cdot) : \mathbb{R} \mapsto \mathbb{R}$ is a strictly convex twice continuously differentiable nonnegative function
Let $\hat{R}_n(f)$ denote the empirical risk defined by

$$\hat{R}_n(f) = \frac{1}{n} \sum_{i=1}^{n} \ell(Y_i, f(X_i)).$$  \hspace{1cm} (6)

Then, the Empirical Risk Minimizer $\hat{f}^{ERM}$ will be a solution to

$$\hat{f}^{ERM} \in \arg\min_{f \in \mathcal{F}} \hat{R}_n(f).$$  \hspace{1cm} (7)
Let us start with ridge type functions
Ridge type functions

We consider a statistical model of the form

$$\mathbb{E}[Y_i \mid X_i] = f(X_i^t \theta^*), \quad i = 1, \ldots, n,$$

where

- $\theta^* \in \mathbb{R}^p$
- the function $f : \mathbb{R} \mapsto \mathbb{R}$ is assumed increasing
Ridge type functions

- the data $X_1, \ldots, X_n$ will be assumed isotropic and subGaussian
- the matrix

$$X^\top = [X_1, \ldots, X_n]$$

is full rank with probability one.

- for all $i = 1, \ldots, n$, the random vectors $X_i$ are assumed
  - to have a second moment matrix $\mathbb{E}[X_i X_i^t] = I_p$,
  - to have $\ell_2$-norm equal\(^1\) to $\sqrt{p}$.

- the errors $\epsilon_i = Y_i - \mathbb{E}[Y_i]$ are independent subGaussian centered random variables with $\psi_2$-norm upper bounded by $K_\epsilon$.

\(^1\)notice that this is different from the usual regression model, where the columns are assumed to be normalised
Ridge type functions

In order to estimate $\theta^*$, the Empirical Risk Minimizer $\hat{\theta}$ is defined as a solution to the following optimisation problem

$$\hat{\theta} \in \arg\min_{\theta \in \Theta} \hat{R}_n(\theta) \quad (10)$$

with

$$\hat{R}_n(\theta) = \arg\min_{\theta \in \Theta} \frac{1}{n} \sum_{i=1}^{n} \ell(Y_i - f(X_i^t \theta)). \quad (11)$$

Moreover, we assume that $\ell'(0) = 0$ and $\ell''$ is upper bounded by a constant $C_{\ell''} > 0$. 
Let us concentrate on Ridge type functions

**Theorem**

Assume that $\hat{\theta}$ is near interpolating, i.e. $|Y_i - f(X_i^\top \hat{\theta})| \leq \varepsilon$. Let $\hat{\theta}^\circ$ denote the minimum norm near interpolating solution to the ERM problem, i.e.

$$\argmin_{\theta} \|\theta\|_2 \quad \text{subject to} \quad \varepsilon_{\text{min}} \leq |Y_i - f(X_i^\top \hat{\theta})| \leq \varepsilon_{\text{max}}, \quad (12)$$

$i = 1, \ldots, n$, for some $\varepsilon_{\text{min}}, \varepsilon_{\text{max}} \geq 0$.

Assume that $f^{-1}$ is $C_{f^{-1}}$-Lipschitz on the set

$$\{z \mid \varepsilon_{\text{min}} \leq |Y_i - f(z)| \leq \varepsilon_{\text{max}}, i = 1, \ldots, n\}.$$
Theorem

Then, under technical assumptions, for any constant $\gamma > 0$, we have

$$|f(X_{n+1}^\top \hat{\theta}^\circ) - f(X_{n+1}^\top \theta^*)| \leq \frac{2n C_f C_f^{-1}}{\sigma_{\min}(X)} \varepsilon_{\text{max}} + t K \|\theta^*\|_2$$

$$+ t \frac{C K X K_{\varepsilon} (\sqrt{n} + 1)}{((1 + \alpha) \sqrt{p} - C K X \sqrt{n})}$$

$$+ t K_{\varepsilon} + t \frac{6 \sqrt{C C_{\ell''}} C_{f'} K_{\varepsilon} \sqrt{n}}{\delta(r)((1 - \alpha) \sqrt{p} - C K X)},$$

with probability at least

$$1 - 2 \exp(-c_{K X} \alpha^2 p) - \exp(-n/2) - \exp(-c_{K X} p) - 3 \exp(-t^2/2).$$
Theorem

where $r$ is a solution of

$$ r = \frac{C(\ell'', f', \varepsilon) \sqrt{n}}{\delta(r) \left( (1 - \alpha) \sqrt{p} - C_{K_X} \sqrt{n} \right)}. $$

(13)
A handy result from Neuberger about the distance of the solution of a zero finding problem, i.e. consisting in solving

$$F(\hat{f}) = 0,$$

to the initial guess $f^*$. 

---

**The Continuous Newton's Method, Inverse Functions, and Nash-Moser**

J. W. Neuberger

1. **INTRODUCTION.** The conventional Newton's method for finding a zero of a function $F : \mathbb{R}^n \rightarrow \mathbb{R}^n$, assuming that $(F'(y))^{-1}$ exists for at least some $y$ in $\mathbb{R}^n$, is the familiar iteration: pick $z_0$ in $\mathbb{R}^n$ and define

$$z_{k+1} = z_k - (F'(z_k))^{-1}F(z_k) \quad (k = 0, 1, 2, \ldots),$$

hoping that $z_1, z_2, \ldots$ converges to a zero of $F$. What can stop this process from finding a zero of $F$? For one thing, there might not be a zero of $F$. For another, the process might terminate for some integer $k$ in the event that $F'(z_k)$ does not have an inverse.

A domain of attraction corresponding to a given root of $F$ consists of the set of all starting values $z_0$ that lead, through convergence of $z_1, z_2, \ldots$ to this root. Newton's
Suppose that $r > 0$, that $\theta^* \in \mathbb{R}^p$ and that the map $F$ is continuous on $\overline{B}_r(\theta^*)$, with the property that for each $\theta$ in $B_r(\theta^*)$ there exists a vector $d$ in $\overline{B}_r(0)$ such that,

$$\lim_{t \downarrow 0} \frac{F(\theta + td) - F(\theta)}{t} = -F(\theta^*).$$

Then there exists $u$ in $\overline{B}_r(\theta^*)$ such that $F(u) = 0$.  

(14)
Since the loss is twice differentiable, the empirical risk $\hat{R}_n$ is itself twice differentiable. The Gradient of the empirical risk is given by

$$\nabla \hat{R}_n(\theta) = -\frac{1}{n} \sum_{i=1}^{n} \ell'(Y_i - f(X_i^t \theta)) f'(X_i^t \theta) X_i$$

$$= -\frac{1}{n} X^t D(\nu) \ell'(\epsilon)$$

where $\ell'(\epsilon)$ is to be understood componentwise, and

$$\nu_i = f'(X_i^t \theta) \quad \text{(15)}$$

and the Hessian is given by

$$\nabla^2 \hat{R}_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} \left( \ell''(Y_i - f(X_i^t \theta)) f'(X_i^t \theta)^2 - \ell'(Y_i - f(X_i^t \theta)) f''(X_i^t \theta) \right) X_i X_i^t.$$
The Deep Neural Network case
Assumption

The sample satisfies the following separation

\[ \min_{i,i'=1}^{n} \|X_i - X_{i'}\|_2 \geq cn^{-1/\nu} \]  \hspace{1cm} (17)

with probability larger than or equal to 1 - \(\delta\), for some positive constants \(c\), \(\nu\) and for \(\delta \in (0, 1)\).

The Holder exponent \(\nu\) is usually interpreted as a surrogate for the intrinsic dimension of the data manifold. E.g., this intrinsic dimension was estimated to be less than 20 for the MNIST dataset.
Here is a Banach space version of the Neuberger theorem.

**Theorem (Neuberger’s theorem)**

Suppose that $\mathcal{B}$, $\mathcal{J}$, and $\mathcal{K}$ are three Banach spaces and that $\mathcal{B}$ is compactly embedded in $\mathcal{J}$.

Suppose that $F : \mathcal{B} \to \mathcal{K}$ is continuous with respect to the topologies of $\mathcal{J}$ and $\mathcal{K}$.

Suppose that $f \in \mathcal{B}$, that $r > 0$, and that for each $g$ in $\mathcal{B}_r(f)$, there is an $h$ in $\overline{\mathcal{B}}_r(0)$ such that

$$\lim_{t \to 0^+} \frac{1}{t} (F(g + th) - F(g)) = -F(f).$$

Then there is $\hat{f}$ in $\overline{\mathcal{B}}_r(f)$ such that $F(\hat{f}) = 0$.

For $r > 0$ and $u$ in $\mathcal{B}$, $\mathcal{B}_r(u)$ and $\overline{\mathcal{B}}_r(u)$ will denote the open and closed balls in $\mathcal{B}$, respectively, with center $u$ and radius $r$. 
Theorem (Neuberger’s theorem for ERM)

Suppose that $r > 0$, that $\theta^* \in \mathbb{R}^p$ and that the Jacobian $D \hat{R}_n(\cdot)$ is a continuous map on $B(\theta^*, r)$ with the property that for each $\theta$ in $B(\theta^*, r)$ there exists a vector $d$ in $B(0, r)$ such that,

$$
\lim_{t \downarrow 0} \frac{D \hat{R}_n(\theta + td) - D \hat{R}_n(\theta)}{t} = -D \hat{R}_n(\theta^*).
$$

(18)

Then there exists $u$ in $B(\theta^*, r)$ such that $D \hat{R}_n(u) = 0$. 
We recall that $f \in \mathcal{F}$, and $d' \in \mathcal{B}$ such that $\mathcal{F} \subset \mathcal{B}$. Let us compute the directional derivative of $\hat{R}_n$

$$D\hat{R}_n(f) \cdot h' = \lim_{t \to 0} \frac{\hat{R}_n(f + th') - \hat{R}_n(f)}{t} = \lim_{t \to 0} \frac{1}{n} \sum_{i=1}^{n} \ell(Y_i, f(X_i) + t h'(X_i)) - \ell(Y_i, f(X_i))}{t}$$

$$= \lim_{t \to 0} \frac{\frac{1}{n} \sum_{i=1}^{n} \partial_2 \ell(Y_i, f(X_i)) t h'(X_i) + c \partial_2^2 \ell(Y_i, f(X_i)) t^2 h'^2(X_i)}{t}$$

with $c \in [0, 1]$, and thus

$$D\hat{R}_n(f) \cdot h' = \frac{1}{n} \sum_{i=1}^{n} \partial_2 \ell(Y_i, f(X_i)) h'(X_i).$$
In the same spirit, we get

\[ D^2 \hat{R}_n(f) \cdot (h', h) = \frac{1}{n} \sum_{i=1}^{n} \partial^2_2 \ell(Y_i, f(X_i)) \, h'(X_i) h(X_i). \]
Based on these computations, Neuberger’s theorem resorts to obtaining a bound on the norm of an appropriate solution $h$ to the following linear system

\[
\frac{1}{n} \sum_{i=1}^{n} \partial_{2}^{2} \ell(Y_i, f(X_i)) \ h'(X_i) h(X_i) = -\frac{1}{n} \sum_{i=1}^{n} \partial_{2} \ell(Y_i, f^*(X_i)) h'(X_i)
\]

for all $f \in B_r(f^*)$ and for all $h' \in B$. 
The idea is now to **decouple the problem** and

- **first solve it in a Sobolev space**, and then
- **approximate the solution by a deep neural network**

Simultaneous Neural Network Approximation for Smooth Functions

**Abstract**

We establish in this work approximation results of deep neural networks for smooth functions measured in Sobolev norms, motivated by recent development of numerical solvers for partial differential equations using deep neural networks. Our approximation results are nonasymptotic in the sense that the error bounds are explicitly characterized in terms of both the width and depth of the networks simultaneously with all involved constants explicitly determined. Namely, for \( f \in C^s([0,1]^d) \) we show that deep ReLU networks of
Theorem

Suppose that \( f^* \in C^s([0,1]^d) \) with \( s > 1 \in \mathbb{N}^+ \) satisfies
\[
\| \partial^\alpha f \|_{L^\infty([0,1]^d)} < 1 \quad \text{for any } \alpha \in \mathbb{N}^d \text{ with } |\alpha| \leq k.
\]
Theorem

Suppose that $f^* \in C^s([0,1]^d)$ with $s > 1 \in \mathbb{N}^+$ satisfies

\[ \| \partial^\alpha f \|_{L^\infty([0,1]^d)} < 1 \text{ for any } \alpha \in \mathbb{N}^d \text{ with } |\alpha| \leq k. \]

Let $\hat{f}$ denote any estimator of $f^*$. 
Theorem

Suppose that $f^* \in C^s([0,1]^d)$ with $s > 1 \in \mathbb{N}^+$ satisfies

$$
\| \partial^\alpha f \|_{L^\infty([0,1]^d)} < 1 \text{ for any } \alpha \in \mathbb{N}^d \text{ with } |\alpha| \leq k.
$$

Let $\hat{f}$ denote any estimator of $f^*$. Then there exists a neural network $f_{\hat{W}}$ such that

$$
\| f_{\hat{W}} - \hat{f} \|_{W^{k,p}(\mathcal{D})} \leq 3(k + 1)^d 8^{\kappa - k} \beta_{width}^{-2(\kappa - k)/d} \beta_{depth}^{-2(\kappa - k)/d} \cdot \left( 1 + n^{\frac{k}{\nu}} \max_{|\alpha| \leq K} \| \partial^\alpha \psi \|_{L^\infty([0,1]^d)} \right)
$$

$$
+ 6 \left( \frac{c}{2} \right)^{d/p - k} \ K_\epsilon \ n^{(1 + \frac{k - d/p}{\nu})} \| \psi \|_{W^{k,p}([0,1]^d)}.
$$
Theorem

Suppose that \( f^* \in C^s ([0, 1]^d) \) with \( s > 1 \in \mathbb{N}^+ \) satisfies
\[
\| \partial^\alpha f \|_{L^\infty([0,1]^d)} < 1 \text{ for any } \alpha \in \mathbb{N}^d \text{ with } |\alpha| \leq k.
\]

Thus there is a deep network which does as well as any estimator \( \hat{f} \) of \( f^* \).

The architecture constraints on this network are

\[
\text{width} \quad 16\kappa^{d+1} d (\beta_{width} + 2) \log_2(8\beta_{width})
\]

and depth
\[
27\kappa^2 (\beta_{depth} + 2) \log_2(4\beta_{width}).
\]
Sketch of the proof
Notice that for all $f \in B_s(f_{W^*})$, we have

$$\frac{1}{n} \sum_{i=1}^{n} \frac{\partial \ell}{\partial_2} (Y_i, f(X_i)) \ h'(X_i) = -\frac{1}{n} \sum_{i=1}^{n} (Y_i - f(X_i)) \ h'(X_i),$$

and that

$$\frac{1}{n} \sum_{i=1}^{n} \frac{\partial^2 \ell}{\partial_2^2} (Y_i, f(X_i)) \ h'(X_i) h(X_i) = \frac{1}{n} \sum_{i=1}^{n} h'(X_i) h(X_i).$$

Then, using the fact that $\ell$ is the $\ell^2_2$ loss, Neuberger’s condition reads

$$\frac{1}{n} \sum_{i=1}^{n} h'(X_i) h(X_i) = \frac{1}{n} \sum_{i=1}^{n} h'(X_i) (Y_i - f_{W^*}(X_i)).$$
One possible solution can be obtained by setting

\[ h(X_i) = Y_i - f_{W^*}(X_i) = \varepsilon_i \]

\( i = 1, \ldots, n \), i.e. using a noise interpolating solution.

One simple option is to take

\[ h(x) = \sum_{i=1}^{n} \varepsilon_i \psi \left( \frac{x - X_i}{\sigma} \right) \]

where \( \psi : \mathbb{R}^p \to \mathbb{R} \) is a kernel function and \( \sigma > 0 \) is a bandwidth.
Here, $\psi$ denotes the bump function

$$
\psi(x) = \begin{cases} 
\exp \left( 1 - \frac{1}{1 - \|x\|_2^2} \right) & \text{if } \|x\|_2^2 \leq 1, \\
0 & \text{otherwise}
\end{cases}
$$

and let $\psi_\sigma = \psi(\cdot/\sigma)$.

Let $\psi_\sigma = \psi(\cdot/\sigma)$. 
Now, observe that, based on Assumption 1, the functions $\psi((x - X_i)/\sigma)$, and their successive derivatives up to $k$, $i = 1, \ldots, n$, have disjoint supports for with probability larger than or equal to $1 - \delta$ as long as $\sigma \leq cn^{-1/\nu}$.

We thus obtain that

$$\|h\|_{B} \leq \|\epsilon\|_1 \|\psi_{\sigma}\|_{B}$$

Moreover, as is well known for subGaussian vectors, the norm is controlled by

$$\|\epsilon\|_2 \leq 6K_{\epsilon}n.$$ 

with probability at least $1 - \exp(-n)$, combining the conclusion of Theorem 13 follows from Neuberger’s Theorem 8.
The proof for the deep neural network case is completed by using the approximation result of Hon and Wang.

Abstract

We establish in this work approximation results of deep neural networks for smooth functions measured in Sobolev norms, motivated by recent development of numerical solvers for partial differential equations using deep neural networks. Our approximation results are nonasymptotic in the sense that the error bounds are explicitly characterized in terms of both the width and depth of the networks simultaneously with all involved constants explicitly determined. Namely for $f \in C^s([0,1]^d)$ we show that deep ReLU networks of
○ The number of layers may have to increase logarithmically with the number of samples

○ The total number of parameters blows up polynomially in the number of samples and exponentially in the dimension of the problem
Conclusion and perspectives
- This simple exercise in using quantitative zero finding theorems such as Neuberger’s theorem shows that we can easily prove results that do not blow up with the number of layers with interpolating networks.

- We can easily study local minimisers as well using the same technique.

- We would need to explore approximation theory in unusual/non standard directions:
  - Improve the Hon and Wang theorem by introducing the constraint that the network be a flat minimiser.
  - This would explain that Stochastic Gradient methods can find the correct approximation with large probability (?)
